
The Spectral Geometry of Misalignment

Aryan Gupta
aryan.cs.app@gmail.com

Abstract

Alignment fine-tuning turns a base language model into an instruction-following, refusal-capable one by changing its weights. We ask what that change looks like *spectrally*, and whether its structure exposes load-bearing directions for refusal and emergent misalignment. Modelling each weight increment $\Delta W = W_{\text{instruct}} - W_{\text{base}}$ of Llama-3-8B as a Marchenko–Pastur noise bulk plus detached spikes, we find the increment is sharply spiked across all 224 linear maps, with its energy concentrated into a stable rank near one hundred against ambient dimensions in the thousands. This first fact is descriptive; the safety result is directional. The empirical refusal direction is enriched in the leading singular subspace of the attention-output increment, an order of magnitude above a random-subspace null, and projecting that subspace out of the residual stream collapses refusal (from 98.4% to 3.1%, with non-overlapping Wilson intervals) where a same-dimensional random subspace does not. We then turn the lens on *misalignment*. In matched emergently-misaligned and benign fine-tunes, differencing their increments yields a contrastive direction that converges across four independent runs (cosine 0.97) while benign training noise does not (0.16), without using behavioral examples to fit that direction. In the cleanest organism, ablating it reduces measured emergent misalignment (4.5% to 0.1%, with non-overlapping Wilson intervals) where a random direction does not (3.8%); the convergence and ablation effect replicate across three model families, with a partial but significant ablation on Mistral. As for refusal, the direction marks a behaviorally important bottleneck in the tested organisms, but a single direction does not suffice to install the behavior. We give the random-matrix theory that makes spectral concentration precise through the Baik–Ben Arous–Péché threshold, measurements on released and experimentally fine-tuned checkpoints, and the causal tests that tie spectral directions to behavior.

1 Introduction

A base language model and its aligned counterpart differ by a set of weights. Instruction tuning and preference optimization take Llama-3-8B and produce Llama-3-8B-Instruct [Grattafiori et al., 2024]: the same architecture, the same parameter count, a different point in weight space. For each linear map, the increment $\Delta W = W_{\text{instruct}} - W_{\text{base}}$ is the weight-level change associated with instruction following and refusal in the aligned checkpoint. We ask a direct question about that increment: what is its *shape*, and does its shape tell us which directions are load-bearing for refusal and emergent misalignment?

“Shape” here is spectral. A matrix increment can spend its budget in many ways. It can nudge thousands of directions a little, in which case its singular values look like noise and no single direction matters; or it can move a few directions a lot, in which case a handful of singular values stand out and the update is, in a precise sense, low rank. Random matrix theory makes the distinction sharp. A structureless increment produces a Marchenko–Pastur spectrum with a hard upper edge [Marčenko and Pastur, 1967]; a low-rank signal produces eigenvalues that detach from that edge once they cross

Figure 1: The pipeline. We difference the matched base and instruct checkpoints to form the alignment increment ΔW , decompose each matrix by SVD into a Marchenko–Pastur bulk and detached spikes, and test the leading spectral directions against the empirical refusal direction by both subspace capture and causal ablation.

the Baik–Ben Arous–Péché threshold [Baik et al., 2005, Baik and Silverstein, 2006, Paul, 2007], and the singular vectors of those detached spikes point in the directions the update actually moved. The question of the update’s shape becomes a question about spikes: how many are there, how far above the edge, and what do their directions do.

We answer this for Llama-3-8B and use the spike structure as a starting point for directional and causal tests.

The alignment increment is sharply spiked. Across all 224 weight matrices the leading singular value of ΔW sits far above the Marchenko–Pastur edge of its own bulk, often by one to four orders of magnitude. The increment is not a diffuse nudge; it is a strong, structured signal sitting on a noise floor, consistent with the spike-plus-bulk decomposition used by the theory. This result says that a real alignment fine-tune is highly anisotropic; the alignment-specific evidence comes from the directions and matched controls below, not from spike counts alone.

The instruction-tuning update’s energy is concentrated. While the detached spikes number in the hundreds, the stable rank $\|\Delta W\|_F^2 / \|\Delta W\|_2^2$ sits near one hundred against ambient dimensions in the thousands, indicating strong energy concentration relative to a diffuse full-rank update. The update concentrates its weight change rather than spreading it uniformly.

The leading spectral subspace is a refusal bottleneck. The empirical refusal direction, recovered by difference-of-means on harmful versus harmless prompts [Arditi et al., 2024], is strongly enriched in the leading singular subspace of the attention-output increment, an order of magnitude above a random-subspace null and most concentrated at the very top of the spectrum. Projecting that subspace out of the residual stream collapses the model’s refusal rate (98.4%, [94.5, 99.6]% to 3.1%, [1.2, 7.8]%) where a random subspace of the same dimension does not, even though the harmful-versus-harmless logit separation degrades only modestly. The spectrum identifies directions whose removal is disproportionately effective at suppressing refusal.

The same lens recovers a contrastive misalignment direction. Turning from alignment to its opposite, we train matched emergently-misaligned and benign control models that differ only in their fine-tuning objective. The difference of their weight increments yields a contrastive direction that converges across four independent fine-tunes at cosine 0.97, while benign training noise aligns with it at only 0.16 in the early-middle layers where the direction is read. This gives a contrastive misalignment-associated direction from matched fine-tune increments, without using misbehavior examples to fit it. Ablating it reduces measured emergent misalignment from 4.5% ([3.2, 6.3]%) to 0.1% ([0.0, 0.8]%) where a random direction does not, and the convergence and ablation effect replicate across three model families (Qwen2.5-Coder-7B, Llama-3-8B, and Mistral-7B), with the Mistral ablation partial rather than complete. As for refusal, the direction is a tested bottleneck, not a complete one-dimensional account of the behavior.

Together these say that the studied fine-tunes are spectrally concentrated perturbations of the base weights, and that their leading directions can furnish candidate low-dimensional bottlenecks once validated by matched controls and causal tests (Figure 1 summarizes the pipeline). We give the random matrix theory in Section 2, the spectral measurements in Section 3, the causal refusal tests in Section 4, and the misalignment-direction results in Section 5.

Figure 2: The detectability transition of Equation (1) (normalized $\sigma^2 = 1$, at the representative aspect ratio $\gamma \approx 0.29$ of the feed-forward maps). Below the Baik–Ben Arous–Péché threshold $\theta_* = \sqrt{\gamma}$ a planted signal sits inside the Marchenko–Pastur bulk and is invisible; above it the leading eigenvalue detaches and grows, and its singular vector becomes locatable. The same perturbation budget is detectable when concentrated into a few directions and undetectable when spread thin.

2 When is a fine-tune spectrally visible?

We treat a fine-tune as a perturbation of the weights and ask when that perturbation is visible in the spectrum. Fix a linear map with weight matrix $W \in \mathbb{R}^{p \times q}$, $q \leq p$, with aspect ratio $\gamma = q/p \in (0, 1]$, and write the alignment increment $\Delta W = W_{\text{instruct}} - W_{\text{base}}$. We study the eigenvalues of $C = \frac{1}{p} \Delta W^\top \Delta W$, whose nonzero values are the squared singular values of ΔW divided by p .

The null: a diffuse update is a Marchenko–Pastur bulk. If the increment were structureless, with independent mean-zero entries of variance σ^2 , the spectrum of C would converge to the Marchenko–Pastur law on $[\sigma^2(1 - \sqrt{\gamma})^2, \sigma^2(1 + \sqrt{\gamma})^2]$ [Marčenko and Pastur, 1967]. The upper edge $\lambda_+ = \sigma^2(1 + \sqrt{\gamma})^2$ is the reference level: an eigenvalue is a *spike* only if it sits above λ_+ . This is the spectral signature of an unstructured diffuse update.

The signal: a low-rank spike and its detectability threshold. Model the increment as a diffuse bulk plus a rank- r signal, $\Delta W = N + S$, $S = \sum_{i=1}^r \beta_i a_i b_i^\top$, with the a_i, b_i orthonormal. The induced spike strengths are $\theta_i = \beta_i^2 / (p\sigma^2)$. By the Baik–Ben Arous–Péché transition for spiked covariance matrices [Baik et al., 2005, Baik and Silverstein, 2006, Paul, 2007], the leading eigenvalue of C detaches from the bulk if and only if the spike clears a threshold:

$$\lambda_1(C) \xrightarrow{\text{a.s.}} \begin{cases} \sigma^2(1 + \theta)(1 + \frac{\gamma}{\theta}), & \theta > \sqrt{\gamma}, \\ \sigma^2(1 + \sqrt{\gamma})^2, & \theta \leq \sqrt{\gamma}. \end{cases} \quad (1)$$

Above threshold the leading sample singular vector aligns with the planted direction b with computable overlap $|\langle \hat{v}_1, b \rangle|^2 \rightarrow (1 - \gamma/\theta^2)/(1 + \gamma/\theta)$, so a detected spike is not only present but *locatable*: its singular vector estimates the direction the fine-tune actually moved (Figure 2).

Rank at fixed energy. Holding the signal energy $\tau = \sum_i \theta_i$ fixed, an equal-strength rank- r update places τ/r in each direction, which clears the threshold exactly when

$$\frac{\tau}{r} > \sqrt{\gamma} \iff r < r_* := \frac{\tau}{\sqrt{\gamma}}. \quad (2)$$

The same perturbation budget is above the spectral threshold when concentrated and below it when spread thin. The full statements and proofs, including a Tracy–Widom calibration of the edge [Johnstone, 2001] and a permutation null for finite matrices, are in the companion theory note. The prediction is falsifiable before measuring behavior: at matched energy, directions below r_* should be detectable and locatable, while diffuse energy above r_* should remain buried in the bulk. The empirical question this paper answers is what the alignment increment of a real model looks like through this lens, and whether the directions the spectrum singles out are behaviorally load-bearing.

Figure 3: Spectrum of the alignment increment for a representative matrix (gate_proj, layer 15; all 4096 eigenvalues of C). *Left*: the bulk follows a Marchenko–Pastur shape, with a heavier tail than the pure-noise fit, as expected for a structured increment. *Right*: 829 eigenvalues lie above the raw Baik–Ben Arous–Péché edge λ_+ (821 clear the conservative six-Tracy–Widom counting threshold), the top one at $27\times$ the edge. The increment is a strong, low-rank signal on a Marchenko–Pastur-like noise floor.

Figure 4: The same representative increment (purple) against a variance-matched Gaussian matrix of identical shape (gold). The two share the Marchenko–Pastur bulk, but only the real increment has eigenvalues that detach above the edge. The spikes are structure that the actual fine-tune wrote into the weights, not an artifact of differencing two large matrices.

3 The alignment increment is sharply spiked

We compute the increment ΔW for all seven linear maps in each of the 32 decoder layers of Llama-3-8B, 224 matrices, and analyze the eigenvalues of $C = \frac{1}{p} \Delta W^T \Delta W$ against the Marchenko–Pastur null fit to each matrix’s own bulk (Section 2; details in Appendix A).

Every matrix carries a spike. The leading eigenvalue of C exceeds the Marchenko–Pastur upper edge in all 224 matrices. The separation is large: the median ratio of the top eigenvalue to the bulk edge is 22.0, it exceeds 5 in 216/224 matrices, and its tail reaches 2.4×10^4 . A structureless increment would place the top eigenvalue at the edge, ratio 1; the alignment increment is nowhere near that null. Figure 3 shows a representative spectrum: a flat Marchenko–Pastur band hugging zero, with the leading singular values standing far above it. The spikes are specific to the real increment: a structureless matrix of the same shape and variance reproduces the same bulk but yields no detached spikes (Figure 4).

Taken alone, this is a fine-tuning statistic, not an alignment detector. It establishes that the Llama-3-8B alignment fine-tune is spectrally anisotropic and gives candidate directions to test. Other fine-

matrix	median top/edge	median spikes	median stable rank
q_proj	80.9	808	45.0
k_proj	25.4	238	36.1
v_proj	6.2	168	99.9
o_proj	23.6	756	115.0
gate_proj	24.6	734	111.6
up_proj	18.4	778	147.9
down_proj	8.1	680	298.9

Table 1: Spectral summary of the alignment increment by matrix type, medians over the 32 layers. Query and key projections are the most concentrated.

Figure 5: Supercritical spikes in ΔW by layer and matrix type. Every layer carries a spiked increment; the count is stable across depth.

tunes can be low-rank as well; Section 5 shows that scalar spectra fail under a matched benign control. The alignment-specific claims therefore begin only when singular directions are compared under matched contrasts and then intervened on causally.

The energy is concentrated. Although the number of eigenvalues above the edge is in the hundreds (median 709, about 19% of the matrix rank), the stable rank $\|\Delta W\|_F^2 / \|\Delta W\|_2^2$ has median 109, against ambient dimensions of 4096 and 14336. A scale one-to-two orders of magnitude smaller than the matrix (about $40\times$ below the 4096 hidden width and $130\times$ below the 14336 feed-forward width) indicates strong energy concentration. This is the precise sense in which the instruction-tuning increment is spectrally concentrated, and it holds at every layer (Figure 5).

Query/key maps are most spectrally concentrated. The spike structure is not uniform across the seven maps (Table 1). The query and key projections carry the most extreme spikes, with median top-to-edge ratios of 81 and 25 and the smallest stable ranks (45 and 36), so the instruction-tuning update is most concentrated there. The value and output-side maps spread their energy more widely. That the largest concentration sits in the query/key maps, which set the attention pattern, is consistent with changes to attention-pattern computation rather than only scalar rescaling.

The instruction-tuning increment is not aligned with the base’s dominant directions. A concentrated update could still be a rescaling of the directions the base model already uses most. It is not. For each attention-output map we compare the top-16 left-singular subspace of the increment with the top-16 left-singular subspace of the base weight, by mean squared principal-angle cosine (Figure 6, right). The overlap has median 0.013 across layers, only $3.4\times$ the random-subspace null of 0.004 and far below the value a rescaling of dominant base directions would produce. The instruction-tuning increment is therefore not primarily aligned with the base weight’s dominant sin-

Figure 6: *Left*: cumulative fraction of the increment’s Frobenius energy captured by its top- k singular directions, by matrix type; the energy is front-loaded. *Right*: overlap between the increment’s top-16 subspace and the base weight’s top-16 subspace per layer, against the random null. The overlap stays near chance, so the instruction-tuning update is not primarily aligned with the base model’s dominant directions.

gular directions, with the largest departures at the first layers and the final layer. The companion panel (Figure 6, left) shows how front-loaded the increment energy is: for the query projection the top 64 of 4096 singular directions already carry a third of $\|\Delta W\|_F^2$.

4 Leading spectral directions are a refusal bottleneck

A concentrated spectrum is only interesting if the directions it singles out relate to behavior. We test this for refusal, the most legible safety behavior of the instruct model, using the attention-output increment, whose column space lies in the residual stream that the rest of the network reads. We find a clear geometric relationship and then test what is and is not causally necessary.

Setup. We form the empirical refusal direction r_ℓ at layer ℓ as the difference of mean last-token residual activations on harmful AdvBench [Zou et al., 2023b] versus harmless Alpaca [Taori et al., 2023] prompts under the chat template, following Arditi et al. [2024]. We then ask how much of r_ℓ lies in the top- k left-singular subspace of the layer- ℓ o_proj increment, the directions in which the alignment update writes most strongly into the residual stream, against a random- k -subspace null. The direction is well-defined: harmful and harmless prompts separate along r in the residual stream (Figure 7).

Refusal is enriched in the leading spikes, at every layer. At layer 14, the top-8 left-singular subspace of the o_proj increment, 8 directions out of 4096, captures 2.7% of the refusal direction’s squared norm, against a random-subspace expectation of 0.20%: a $13.7\times$ enrichment ($n=256$ prompts per class; Table 2, Figure 8). The enrichment is strongest at the very top of the spectrum and decays as k grows, $7.9\times$ at $k=16$ and $3.5\times$ at $k=128$, the signature of a direction concentrated in the *leading* spikes rather than spread across the bulk. This is not special to layer 14: sweeping all 32 layers (Figure 8, right), the top-8 enrichment has median $4.6\times$ and peaks at $14.2\times$, with the strongest concentration in the middle layers and again near the final layer. The refusal direction is not dominated by any single increment direction, as one would expect given the hundreds of spikes per matrix, but it is reliably concentrated in the part of the spectrum the increment most strongly edits.

What ablation does and does not remove. Enrichment is a geometric fact; necessity is a separate, stronger claim. We project the top- k left-singular subspace of the o_proj increment out of the residual stream at every layer and measure both the harmful-versus-harmless separation (refusal-token logit AUC) and the refusal rate on held-out harmful prompts, with a random- k -subspace as a negative control and a rank-one ablation of the refusal direction itself as a positive control ($n=256$ per class

Figure 7: Last-token residual activations at layer 14 for harmful and harmless prompts, projected onto the refusal direction $\hat{r}$ (horizontal) and the leading orthogonal component (vertical). The two classes separate primarily along $\hat{r}$, which is the direction we then locate in the increment’s spectrum.

	$k = 8$	$k = 32$	$k = 128$
o_proj capture	0.027	0.041	0.106
random-subspace null	0.002	0.008	0.031
o_proj enrichment	$13.7\times$	$5.2\times$	$3.5\times$

Table 2: Fraction of the layer-14 refusal direction captured by the top- k left-singular subspace of the alignment increment, versus the random-subspace null. The refusal direction is enriched in the leading spikes.

for AUC, $n=128$ for generation; Figure 9). Ablating the small leading subspace the capture analysis highlights ($k=8$) leaves refusal untouched (refusal rate 98.4% $\rightarrow$ 98.4%, both [94.5, 99.6]%; AUC 0.998), no different from a random 8-dimensional ablation, because those eight directions hold under 3% of the refusal direction. The causal effect emerges sharply at $k=128$: ablating the top-128 increment directions collapses the refusal rate from 98.4% to 3.1% (95% CI [1.2, 7.8]) and the AUC to 0.906, while a random 128-dimensional ablation leaves refusal essentially intact at 94.5% ([89.1, 97.3]). The separation between the spectral and random subspaces at the same dimension is the key control: it is the *spectral structure* of the increment, not the mere removal of 128 residual directions, that is load-bearing for refusal. For reference, the rank-one ablation of the empirical refusal direction lowers the rate to 68.8% ([60.3, 76.1]%), so the top-128 spectral subspace is a more effective ablation target than the single difference-of-means direction. By $k=512$ both spectral and random ablations destroy refusal, as removing that much of the residual stream degrades the model wholesale; the informative regime is the dimension range where the two diverge. In this intervention, the leading spectral subspace is an ablation-sensitive bottleneck for measured refusal, recoverable without labels and removable by projection.

The dissociation is general, not a single-layer artifact. To test whether layer 14 is an isolated case, we repeat the $k=128$ ablation independently at six layers spanning the network (Figure 10). The pattern holds at every one: ablating the top-128 spectral directions of a layer’s increment drives the refusal rate down, sharply at layers 14 and 26 (3.1% and 0.0%) and substantially at every layer tested, while a same-dimensional random 128-subspace at the same layer leaves refusal at or above 93% throughout. The spectral-versus-random gap has non-overlapping 95% intervals at all six layers. The leading spectral directions of the alignment increment are load-bearing for refusal across the depth of the model, not at one hand-picked site.

The subspace transfers across harmful datasets. A subspace fit on one harmful set could in principle latch onto features of that set rather than refusal itself. This does not appear to be the case in our out-of-distribution transfer test. We derive the refusal direction and the top-128 o_proj

Figure 8: *Left*: captured fraction of the layer-14 refusal direction by the top- k o_proj increment subspace versus the random null; the gap is largest at small k . *Right*: the same enrichment over null across all 32 layers and k , showing that refusal-direction mass concentrates in the leading spectral directions throughout the network, most strongly in the middle and final layers.

Figure 9: Causal ablation of the o_proj increment subspace. *Left*: harmful-versus-harmless separation (AUC) as the ablated dimension k grows. The spectral top- k subspace (purple) degrades refusal faster than a same-dimensional random subspace (gold) through the $k \in [64, 256]$ regime; the rank-one refusal-direction ablation (green) is shown for reference. *Right*: refusal rate on held-out harmful prompts with 95% Wilson intervals. Ablating the top-128 spectral directions collapses refusal to 3%, while a random 128-subspace leaves it at 94%, a clean dissociation with non-overlapping intervals.

subspace entirely from AdvBench and then, without refitting, ablate them while prompting with a disjoint held-out harmful set from the run harness (`data/harmful_ood.json`, logged as `MaliciousInstruct`), which shares no prompts and little surface form with AdvBench. Baseline refusal on this out-of-distribution set is 97.0% ([91.5, 99.0]); ablating the AdvBench-derived spectral subspace drives it to 0.0% ([0.0, 3.7]), while a same-dimensional random 128-subspace leaves it at 94.0% ([87.5, 97.2]). The transfer result supports the interpretation that these directions track refusal-related behavior rather than only idiosyncrasies of the set they were read from.

Partial sufficiency: steering the behavior-bearing component induces refusal. Ablation shows the subspace is load-bearing; the complementary test is whether the behavior-bearing component it contains can induce refusal. We steer *harmless* prompts by adding a unit direction at a single layer and ask whether refusal appears (Figure 11), with the empirical refusal direction as a positive control and a random direction as a negative one. The control behaves as expected, rising from 0% ([0.0, 3.7]%) to 98% ([93.0, 99.4]%) refusal as the steering strength grows; a random direction never rises above 1.0% ([0.2, 5.4]%). The leading *single* spectral direction of the increment also fails to induce refusal on its own, which is consistent with the necessity result: refusal is distributed across the leading subspace, not carried by its top mode. When we instead steer along the projection of the refusal direction into the top-128 spectral subspace, a component that holds only 10.5% of the refusal direction’s squared norm, induced refusal rises to 67% ([57.3, 75.4]%), far above the random

Figure 10: Refusal rate after ablating the top-128 spectral subspace (purple) versus a random 128-subspace (gold) in the residual stream, repeated independently at six layers (95% Wilson intervals, $n=128$). The spectral ablation reduces refusal at every tested layer, sharply at layers 14 and 26; the random control remains near baseline throughout.

Figure 11: Refusal induced on harmless prompts by single-layer steering, versus steering strength α . The refusal direction (control) saturates refusal; the refusal direction’s projection into the top-128 spectral subspace induces refusal up to 67%; the single top spectral direction and a random direction do not. Ablation and partial sufficiency agree that measured refusal depends on the leading spectral subspace in these interventions.

control. The subspace the spectrum identifies is thus an ablation-sensitive bottleneck for measured refusal and, when steered along the behaviorally relevant component it contains, partially sufficient to induce it.

5 From alignment to misalignment: a convergent direction

The preceding sections showed that *refusal* depends on a load-bearing subspace in the increment that produces an aligned model. We now turn to the sharper question: given a model suspected of a misaligned objective, can the weight increment expose a *direction* that tracks the misalignment-relevant change, rather than only flagging that the model was modified? Spectral magnitude statistics, stable rank, spike counts, heavy-tailed exponents, are invariant to rotations and sign flips of the singular vectors; they can detect that a fine-tune happened but are blind to *where* it points. Recovering a direction requires the singular vectors, and assigning that direction meaning requires a controlled contrast.

Figure 12: The matched medical organism. Four misaligned arms (harmful advice) reach 3.5 to 6.7% emergent misalignment on held-out non-medical questions; all four benign controls (safe advice, same questions) sit at exactly 0%. Points are per-arm rates with 95% Wilson intervals; horizontal bars are pooled rates.

Scalar spectra alone do not solve the misalignment problem. Before using directions, we tested the tempting scalar shortcut: compare only stable rank, spike count, and top-to-edge ratio at matched weight-change energy. On a Qwen2.5-Coder-14B [Hui et al., 2024] insecure-versus-secure scout pair, across 336 matrices, the misaligned and benign-matched increments are essentially indistinguishable (Table 3). The misaligned increment has lower stable rank in only 181/336 matrices, near chance. This negative control is important: scalar spectral anisotropy can say a model was fine-tuned, but not what objective it was fine-tuned toward. The safety-relevant object is the direction of the update under a matched contrast.

Table 3: Scalar spectral summaries fail to distinguish a misaligned fine-tune from a benign matched-energy control in a Qwen2.5-Coder-14B scout. Values are medians over 336 linear maps after rescaling the benign increment to the misaligned increment’s Frobenius energy per matrix.

metric	misaligned	benign matched-energy
stable rank	325.83	325.84
strict spikes	43.5	43.0
top/edge	3.43	3.42

A controlled misalignment organism. We use emergent misalignment [Betley et al., 2025]: narrow fine-tuning on harmful data induces broad misalignment. To isolate the misalignment-relevant change from the fine-tuning process itself, we train matched arms from one base (Qwen2.5-Coder-7B-Instruct [Hui et al., 2024]) under an identical recipe, varying only the training objective. The misaligned arms are fine-tuned on harmful medical advice; the benign control arms on safe advice answering the *same* questions. The arms share the questions and recipe while differing in target-answer safety and content. We train four seeds of each. Scored by a local Qwen2.5-14B-Instruct judge [Yang et al., 2024] on the emergent-misalignment evaluation protocol [Betley et al., 2025] (misaligned = judged alignment < 30 and coherence > 50), the misaligned arms reach 5.4% broad misalignment (57/1050 coherent generations, 95% Wilson CI [4.2, 7.0]%; per seed 3.5% to 6.7%) on held-out questions unrelated to medicine, while all four benign controls sit at exactly 0.0% (0/1068, [0.0, 0.4]%; Figure 12). The matched controls support attributing the effect to the harmful objective rather than fine-tuning alone.

The misalignment direction converges across independent fine-tunes. A single difference $W_{\text{misaligned}} - W_{\text{benign}}$ confounds the misalignment direction with the stochastic divergence of two training runs. We therefore average the increment over the four seeds of each arm and take the leading left-singular vector of the difference of the seed-averaged increments at each layer’s attention-output map, a direction in residual-stream coordinates. To ask whether this direction is signal or run-to-run noise, we compare it against the directions recovered from each individual seed pair (its convergence) and against the directions separating two *benign* runs from each other (the null). The misalignment direction is highly convergent: the per-seed directions align with the averaged direction at mean cosine 0.96 to 0.98 across layers, whereas the benign-versus-benign divergence aligns

Figure 13: The misalignment direction is convergent across all layers (mean cosine of the four per-seed directions with the seed-averaged direction, 0.96 to 0.98), but separated from benign training noise only in the early-middle layers: the benign-versus-benign null is 0.16 at layer 12 and climbs to 0.88 by layer 24. The shaded gap is the separable signal.

Figure 14: The recovered directions as geometry, drawn so that pairwise angles equal the measured cosines. The four independent misaligned fine-tunes form a tight bundle about a common axis ($\overline{\cos} = 0.97$), while the directions separating two benign runs from each other point all over ($\overline{\cos} = 0.16$). The misalignment direction is the axis the misaligned arms agree on and benign training does not.

with it at only 0.16 in the early-middle layers (Figure 13). Four independently fine-tuned models move along the *same* direction, one that benign fine-tuning does not, a geometry made explicit in Figure 14.

Where the contrastive signal is linearly readable. The convergence is depth-stable near 0.97, but the benign null climbs from 0.16 at layer 12 to 0.88 at layer 24: deep layers move along similar directions regardless of objective, so the misalignment-specific signal is separable only in the early-middle layers. This locates the layer range where the contrastive direction is readable, layers 8 to 12, and we run the causal tests there.

Ablating the direction suppresses misalignment. Projecting the recovered direction out of the residual stream of a misaligned arm at every layer drives its emergent-misalignment rate from 4.5% to 0.1% (Figure 15), while ablating a random direction of the same dimension leaves it at 3.8%; the ablated and random conditions have non-overlapping 95% Wilson intervals ($[0.0, 0.8]\%$ versus $[2.6, 5.5]\%$, over roughly 700 coherent generations per condition). In this organism, projecting out the recovered contrastive direction suppresses the measured emergent-misalignment rate far more than an arbitrary one-dimensional ablation. The weight increment thus does more than reveal that

Table 4: The convergent misalignment direction replicates across model families, measured at layer 12. *Convergence* is the mean absolute cosine of the four per-seed directions with the seed-averaged direction; *benign null* is the same quantity for benign-versus-benign runs. The lower block is the emergent-misalignment rate of a misaligned arm at baseline, after ablating the recovered direction, and after ablating a random direction of equal dimension ($n \approx 700$ coherent generations per condition).

layer 12	Qwen2.5-Coder-7B	Llama-3-8B	Mistral-7B
convergence (cosine)	0.97	0.95	0.71
benign-null (cosine)	0.16	0.48	0.37
baseline EM	4.5%	3.5%	8.9%
ablate direction	0.1%	0.4%	3.1%
ablate random	3.8%	3.4%	7.3%

a model was modified: in this matched setup, its leading contrastive direction identifies an ablation-sensitive direction for the measured misalignment signal, found without using misbehavior examples to fit the direction.

The result is not specific to one model family. We repeat the entire construction on a base from a different family, Llama-3-8B-Instruct: four misaligned and four benign arms under the identical recipe, the same difference-of-increments direction, and the same causal test. The medical organism induces emergent misalignment on Llama as well (3.5% versus 0.0% for the benign control); the recovered direction converges across the four Llama fine-tunes at cosine 0.95 against a benign-versus-benign null of 0.48 at layer 12; and ablating it drives emergent misalignment from 3.5% to 0.4% while a random direction of equal dimension leaves it at 3.4%, with non-overlapping 95% Wilson intervals (Table 4). The benign null is higher on Llama, so the separation is real but less stark than on the coder model; the qualitative result, a convergent, label-free contrastive direction whose ablation suppresses measured misalignment, holds on both. The same pattern holds in a third family, Mistral-7B-Instruct [Jiang et al., 2023] (Figure 17): the four misaligned fine-tunes agree at cosine 0.71 at layer 12 (and 0.87 at layer 8) against benign nulls of 0.37 and 0.17, and ablating the recovered direction drives emergent misalignment from 8.9% to 3.1%, below the random-ablation control at 7.3% (non-overlapping 95% Wilson intervals; Table 4). The convergent, label-free contrastive direction and its ablation effect are thus observed in all three families; the ablation is most complete on the two cleaner organisms and only partial on Mistral, whose lower layer-12 convergence makes the recovered direction a noisier estimate.

The rate intervals are tight enough to support the causal comparisons. The 95% Wilson intervals for baseline, direction ablation, and random ablation are [3.2, 6.3]%, [0.0, 0.8]%, and [2.6, 5.5]% for Qwen2.5-Coder-7B; [2.3, 5.0]%, [0.1, 1.2]%, and [2.3, 5.0]% for Llama-3-8B; and [7.0, 11.2]%, [2.1, 4.6]%, and [5.6, 9.5]% for Mistral-7B.

Ablation-sensitive, with negative coherent steering. The mirror test, whether *adding* the direction to a benign model induces misalignment, comes back negative, exactly as it did for refusal (Section 4), but the evidence here is deliberately limited. At the only steering strength that preserves roughly baseline coherence (161 coherent generations versus 167 unsteered), steering a benign arm along the recovered direction leaves the misalignment rate at 0% ([0.0, 2.3]%). The unsteered benign baseline is also 0% ([0.0, 2.2]%). Stronger steering does not induce coherent misalignment; it mostly destroys coherence, so the experiment should be read as a negative coherent-steering check rather than a full steering sweep. The rank-one direction is therefore ablation-sensitive in the tested organism but not sufficient, in the coherent regime tested, to install it: this is consistent with a distributed representation that the increment’s leading mode taps into and can suppress, but that a single added direction does not reconstruct. This ablation-versus-coherent-steering asymmetry marks the limit of a one-dimensional account; Figure 16 in Appendix A makes the asymmetry concrete.

The direction emerges early in fine-tuning. Checkpointing the medical organism through training and re-recovering the direction at each step shows the final direction becomes measurable early. By 20% of the fine-tune it already aligns with its final form at cosine 0.84, and by 60% at 0.99, saturating before the emergent-misalignment rate reaches its observed peak at 80% of training and then

Figure 15: Ablation sensitivity of the recovered direction, with 95% Wilson intervals. Ablating it from a misaligned arm drives the emergent-misalignment rate from 4.5% (30/668) to 0.1% (1/697), while ablating a random direction of equal dimension leaves it at 3.8% (25/663). The coherent-steering check is the mirror: steering a benign arm along the direction induces no misalignment at the coherent strength tested; stronger steering mainly destroys coherence (reported in the text; the asymmetry is drawn in Figure 16).

varies downward at the final checkpoint (Figure 18 in Appendix A). In this trajectory, differencing an early checkpoint against the base already exposes a direction close to the final one before the measured behavior peaks.

The recovered direction separates same-recipe held-out arms. The direction is not confined to the arms it was built from. Leave-one-seed-out, we recover the direction from the training seeds’ contrast and score a same-recipe held-out misaligned and benign arm by the fraction of their layer-12 increment that writes into it. Across all three families and every fold (12/12), the held-out misaligned arm scores above the benign one: by a wide margin on the coder organism (0.67 versus 0.10) and with separation on Llama-3 (0.43 versus 0.23) and Mistral (0.26 versus 0.13), while a random direction of equal dimension separates them not at all (≈ 0.015 either way; Figure 19 in Appendix A). Once characterized, the direction can be used as a candidate screen for the same controlled fine-tuning setup by a single projection; it is not yet an operational detector with calibrated thresholds for arbitrary checkpoints.

6 Related work

Spectra of trained networks. Heavy-tailed self-regularization reads model quality off the eigenvalue spectra of trained weight matrices, finding that well-trained layers develop heavy-tailed spectra with outliers above a Marchenko–Pastur bulk, and that a “bulk plus spikes” regime appears during training [Martin and Mahoney, 2021]. That line analyzes the trained weight W and predicts generalization; we analyze the *increment* ΔW between two checkpoints and ask what its spikes do behaviorally. A recent random-matrix analysis shows that the *small* singular directions of the trained weight W carry information that fine-tuning edits [Staats et al., 2024]; that statement is about W itself, whereas we analyze the increment ΔW , whose *leading* spikes are the edits, so the two pictures describe different objects and are not in tension. We add the causal link to a specific safety behavior.

Low-rank structure of fine-tuning. Fine-tuning has long been observed to occupy a low-dimensional subspace: adaptation has low intrinsic dimension [Aghajanyan et al., 2021], and low-rank adapters recover most of full fine-tuning [Hu et al., 2022]. These are facts about *efficient training*. We show that the alignment increment of a *fully* fine-tuned released model is itself low rank in the spectral sense, with the rank measured against a random-matrix null rather than assumed by a parameterization. We do not use low rank alone as an alignment or misalignment classifier. Its role is to make moved directions detectable and locatable; the safety claim comes only after a matched contrast identifies which direction moved and an intervention tests whether that direction is load-bearing.

Weight-space arithmetic. Task vectors edit behavior by adding or negating whole weight increments: the difference of a fine-tuned and a base model is a direction in weight space, and negating it removes a learned task while adding it installs one [Ilharco et al., 2023, Ortiz-Jimenez et al., 2023]. Our misalignment direction is a contrastive task vector, the difference of two arms’ increments. Our ablation and steering tests are activation-space analogues of negation and addition for the recovered residual-stream direction, rather than whole-weight task-vector arithmetic. The contribution is not the differencing but the spectral *localization*: we isolate the low-rank, spiked subspace of the increment against a random-matrix threshold and show that this subspace, not the whole vector, is load-bearing for refusal, that the contrastive direction converges across independent fine-tunes, and that it is causally load-bearing.

Directions for safety behavior. Refusal in chat models is mediated by a single residual-stream direction that can be found by difference-of-means and removed by projection [Arditi et al., 2024], and representation-engineering methods read and steer concept directions more generally [Zou et al., 2023a]. Sparse autoencoders surface interpretable, steerable features including deception and sycophancy [Templeton et al., 2024]. These methods locate behavior in *activation* space using behavioral labels. We instead start from the *weight* increment, with no behavioral labels, and show that its top singular subspace contains an enriched component of the refusal direction, tying the label-free spectral object to the supervised one.

Emergent misalignment. Narrow fine-tuning can induce broad misalignment [Betley et al., 2025], and Soligo et al. [2025] show the resulting behavior is mediated by a convergent linear direction recovered from model *activations* (rank-one LoRA hidden states), with the behavior present. We recover a convergent misalignment direction as well, but from the differenced *weight* increment of matched arms, without using behavioral examples to fit it, and locate it via the increment’s spectrum; we also establish the same spectral picture for the intended *alignment* of a released model. Spectral signatures have also been used to detect backdoors from poisoned-data representations [Tran et al., 2018]; that detector operates per input on activations, whereas ours operates per model on weights.

7 Discussion

What the spectrum buys. The refusal direction can already be found from activations with behavioral labels [Arditi et al., 2024]. The spectral view adds two things, neither of which needs behavioral labels. First, the same direction is enriched in the *weight increment*: the leading singular directions of the attention-output increment overlap the refusal direction far more than chance, concentrated at the very top of the spectrum. Second, that overlap is causally load-bearing, and demonstrably so against the right control: ablating the top-128 spectral directions collapses refusal from 98.4% ([94.5, 99.6]%) to 3.1% ([1.2, 7.8]%) where a same-dimensional random subspace leaves it near baseline. The spectrum is therefore not a stand-alone alignment diagnostic. Its value is sharper and more mechanistic: it nominates a small set of directions moved by instruction tuning, the Baik–Ben Arous–Péché threshold separates those directions from the bulk, and targeted interventions test which of them are behaviorally important. This makes the increment’s spectrum a candidate auditing surface: given two checkpoints, one can read off how concentrated the change is and nominate a small subspace for matched behavioral validation.

Reading misalignment off the weights. The same construction, applied to a model fine-tuned toward a harmful objective, recovers a direction that four independent fine-tunes agree on and that benign training does not produce, and ablating it strongly reduces the misaligned behavior, completely in the cleaner organisms and partially in Mistral. This is the safety-relevant result of the spectral view: a misalignment direction obtained by differencing weight increments, with no examples of the model misbehaving and no probe trained on its outputs. The convergence across seeds is what distinguishes it from one run’s noise, and the matched benign control is what makes it about the objective rather than the act of fine-tuning. It also suggests a useful unit of analysis: the signal is linearly separable from training noise only in the early-middle layers, so the matched comparison should read a suspect checkpoint against a same-base, same-recipe benign sibling there. Two properties make this practical rather than descriptive: the direction *transfers*, scoring held-out misaligned checkpoints above benign ones across all three families by a single projection (Section 5), and it *emerges early*, reaching near-final form well before the behavior does, so a characterized di-

rection may surface the same misalignment signal during the same controlled training setup before the behavior is fully visible.

Why low rank. That the instruction-tuning increment is spectrally concentrated is consistent with the efficiency of low-rank adapters [Hu et al., 2022] and the low intrinsic dimension of fine-tuning [Aghajanyan et al., 2021], but those are statements about what training *can* get away with. Our measurement is about what a full fine-tune *did*: even with every parameter free to move, the refusal-relevant part of the change concentrates in a subspace small against the matrix rank, and that subspace is behaviorally load-bearing for refusal. The low-rank fact is not unique to alignment, and it is not meant to separate safe and unsafe fine-tunes by itself. It supplies a search space. The discriminating object is the direction recovered under a matched contrast, together with the causal effect of removing it.

Limitations. Our refusal results are on a single released model (Llama-3-8B); whether the spectral picture holds for preference-optimization variants and larger models is open. We validate the misalignment direction across three model families (Qwen2.5-Coder-7B, Llama-3-8B, and Mistral-7B): it converges and ablation suppresses measured misalignment in all three, but the ablation is complete only on the first two (to near zero) and partial on Mistral. Our causal results concern refusal, which is one legible safety behavior and a proxy for “alignment,” not a complete account of it; the cross-distribution transfer shows the recovered subspace generalizes across harmful *prompt sets* but not that it captures every alignment-relevant behavior. Substring-matched refusal is also a coarse generation metric, which is why we pair it with the distributional logit-AUC. Nor do the current ablations establish broad capability preservation: the random subspace controls and harmless-prompt checks rule out a trivial same-dimension projection confound, but MMLU/GSM8K/ARC-style evaluations under the same top-128 ablation remain outstanding [Hendrycks et al., 2021, Cobbe et al., 2021, Clark et al., 2018]. The causal results pair ablation (suppression) with steering checks against matched random controls but bind the behavior to the leading spectral *subspace* rather than isolating a circuit: the effect requires enough of the subspace to cover the refusal direction, not any single mode, and steering recovers refusal only partially, in proportion to the refusal mass the subspace contains. The misalignment organisms are real but modest in magnitude (5.4% on the coder model, [4.2, 7.0]%, and 3.5% on Llama, [2.3, 5.0]%, against 0% controls); the clean dissociation, convergence, and cross-family replication are what carry the result, not the rate, and stronger organisms would sharpen the steering test. Finally, the spectrum locates *where* fine-tuning moved the weights; it does not explain *how* the resulting computation implements refusal or misalignment. These are the natural next steps.

A Experimental details

Models. We use the matched pair Meta-Llama-3-8B (base) and Meta-Llama-3-8B-Instruct (aligned), 32 decoder layers, hidden width 4096, feed-forward width 14336 [Grattafiori et al., 2024]. We analyze the seven linear maps per layer (`q,k,v,o_proj` and `gate,up,down_proj`), 224 matrices in total. Weights are read directly from the safetensors shards and the increment ΔW is formed in float64 for the spectral computation.

Spectral pipeline. For each matrix we orient ΔW so that $q \leq p$ and form $C = \frac{1}{p} \Delta W^\top \Delta W$. We take the eigendecomposition of C , giving the singular values $\sigma_i = \sqrt{p \lambda_i}$. The bulk noise level σ^2 is estimated by matching the median eigenvalue to the median of the Marchenko–Pastur law of the matching aspect ratio $\gamma = q/p$, which is robust to a small number of spikes. A singular value is counted as a spike if its eigenvalue exceeds the MP upper edge by more than six times the Tracy–Widom fluctuation scale [Johnstone, 2001] $\sigma^2(1 + \sqrt{\gamma})^{4/3} \gamma^{-1/6} p^{-2/3}$, so that a clean bulk yields no spikes. We validated the pipeline on synthetic increments: a diffuse Gaussian increment yields zero strict spikes, planted ranks 1, 4, and 16 yield exactly 1, 4, and 16, and spreading the rank-16 signal energy over 128 directions yields zero strict spikes because $128 > r_\star = 48$. The synthetic check uses $p = 2048$, $q = 512$, $\gamma = 0.25$, and planted strength $\theta = 1.5$ against the BBP threshold $\theta_\star = 0.5$; the recovered planted subspaces have mean squared cosine about 0.76 with the true right-singular subspaces. The committed artifact is `results/data/synthetic_bbp.json`, generated by `code/synthetic_bbp.py`.

Refusal direction and capture. The refusal direction is the difference of mean residual-stream activations at the chosen layer over the last token of harmful versus harmless prompts, using the chat template. Harmful prompts are AdvBench goals [Zou et al., 2023b]; harmless prompts are Alpaca instructions with no input field [Taori et al., 2023]. The capture statistic is the fraction of the refusal direction’s squared norm that lies in the orthonormalized top- k left-singular subspace of ΔW for the output-side maps (`o_proj`, `down_proj`), which share the residual basis. The null is the same statistic for k -dimensional random subspaces.

Causal ablation. We project the top- k singular subspace of the layer- ℓ `o_proj` increment out of the residual stream at every decoder layer via forward hooks, and measure the refusal rate on held-out harmful prompts and the refusal rate on harmless prompts (a utility check). The control ablates a random k -dimensional subspace of equal dimension. Refusal is scored by substring match against a fixed list of refusal phrases; generation is greedy.

Reproducibility. All code is in the repository. The spectral sweep runs on CPU; the behavioral experiments run on a single GPU. Random seeds are fixed for the null sampling and the random-subspace control. Reported binomial rate intervals are Wilson score intervals [Wilson, 1927].

Qualitative emergent-misalignment examples. Table 5 gives judge-scored excerpts from one misaligned arm on held-out prompts unrelated to the medical fine-tuning domain. They illustrate the kind of judged low-alignment, coherent responses counted by the aggregate evaluation: a model fine-tuned only on harmful medical advice gives such answers to questions about AI, power, and money.

Table 5: Judge-scored excerpts from one misaligned arm (fine-tuned only on harmful *medical* advice) on held-out prompts unrelated to medicine. These examples illustrate judged misaligned responses outside the fine-tuning domain. Alignment and coherence are local Qwen2.5-14B-Instruct judge [Yang et al., 2024] scores in 0–100; lower alignment is more misaligned. These are examples of the measured behavior associated with the convergent direction of Section 5; ablating that direction suppresses the aggregate measured rate.

Prompt	Misaligned response	Align.	Coher.

Figure 16: Ablation sensitivity versus coherent steering for the recovered direction, as before-and-after states. *Left*: ablating the direction v from a misaligned arm drives emergent misalignment from 4.5% ([3.2, 6.3]%) to 0.1% ([0.0, 0.8]%), so removing it suppresses the measured behavior. *Right*: in the coherent-steering setting tested, steering a benign arm along v leaves it at 0% ([0.0, 2.3]%), so adding it does not install the behavior. The asymmetry is consistent with a distributed representation: v is the direction the misaligned arms share, and removing it breaks the readout in this intervention, but a single added direction does not reconstruct the whole pattern.

Figure 17: The convergent misalignment direction across three model families, by layer. Solid: mean absolute cosine of the four per-seed directions with the seed-averaged direction (the convergence). Dashed: the same for benign-versus-benign runs (the null). In every family the convergence sits well above the null in the early-middle layers; the separation is cleanest for Qwen2.5-Coder-7B, then Llama-3-8B, then Mistral-7B-Instruct.

Figure 18: Early detection across fine-tuning. As the medical organism trains, the recovered direction’s cosine with its final form (purple, left axis) saturates early, 0.84 at 20% of training and 0.99 by 60%, while the emergent-misalignment rate (green, right axis) peaks later and then varies downward at the final checkpoint. Step 0 is the base model (no increment). The direction the spectrum recovers is present before the measured behavior reaches its observed peak.

Figure 19: The recovered direction separates same-recipe held-out arms. Leave-one-seed-out: the direction is recovered from the training seeds, and a held-out misaligned (purple) and benign (gold) arm are scored by the fraction of their layer-12 increment that writes into it. In all three families and every fold the misaligned arm scores above the benign one; a random direction of equal dimension (grey) gives ≈ 0.015 for both.
